Fronsotepics 5.5: The Shield. Precambrian granite cropping out at Rivière des Rochers, an outlet of Lake Athabasca, northeastern Alberta. Upper Archean and Proterozoic igneous and metamorphic rocks, arrayed in a complex mosaic of tectonic domains, constitute basement for virtually the whole of the Western Canada Sedimentary Basin to the west and south. Photograph by J.G. Godfrey.
Introduction

The complex rock assemblages that form the western margin of the exposed Canadian Shield dip gently beneath the Western Canada Sedimentary Basin. Maps for the Precambrian basement rocks of the Precambrian and tectonic slices of these crystalline rocks are found still farther west in the Cordillera, indicating a greater areal extent prior to Mesozoic and Cenozoic deformation.

To overcome the problems associated with the study of deeply buried rocks, maps from aeromagnetic, gravity, electrical conductivity, and seismic surveys have been used to define the crustal blocks and their boundaries. Thus, the WCSB (Ross et al., this volume, Chapter 4). Although over 4000 exploratory wells have penetrated the Precambrian in Western Canada, the bulk of the geological information on the basement has been derived from the 400 wells cored. Petrography, whole-rock geochemistry, and isotopic age determinations have been carried out on many of these cores. A major constraint on work with the cores is the uneven distribution of sample localities. A high proportion were obtained from the Peace River Arch in northern Alberta. The Precambrian basement is poorly known under deeper, and between shallower, parts of the basin. However, some of the shallower portions, particularly in northern Manitoba, have been actively explored by mining companies. Well over 2500 diamond-drill holes have penetrated the Precambrian under WCSB cover in northern Manitoba.

Previous Work

The decade of intensive exploration following the Leded oil discovery of 1947 provided most of the Precambrian core samples used by Burwash and Krupicka (1969), in their synthesis published in the Geologic History of Western Canada. The advent of K-Ar dating was critical in defining the Archean and Proterozoic blocks of the exposed crust of the Shield (Ross et al., 1965, 1967). The American Association of Petroleum Geologists completed their Basement Rock Project with the publication of the Basement Maturity Index Map and Chart (1967). This incorporated samples supplied by Burwash for the Canadian wells then drilled to basement.

Detailed petrography was combined with whole-rock geochemistry by Burwash and Krupicka (1969, 1970) and Burwash and Culbert (1975) to define the Athabasca mobile belt, a zone of dynamic metamorphism and K-metasomatism extending across northern Alberta. Maps for the Precambrian basement rocks of the Precambrian and tectonic slices of these crystalline rocks are found still farther west in the Cordillera, indicating a greater areal extent prior to Mesozoic and Cenozoic deformation.

Structure

Figure 5.1 shows the configuration of the unconformity at the base of the Precambrian and the Paleozoic strata in the Peace River and Sweetgrass-North Battleford arches, and the intervening Keg River, West Alberta and Williston basins, serve to interrupt the broad southeasterly and northwesterly trends. The high structural relief or subsidence of these features is documented in the chapters which follow.

Prior to burial, differential erosion of the older Precambrian rock units imparted an etched grain to the unconformity. Differences in basement elevation of up to a hundred metres between wells in adjacent townships were noted during compilation of the data base. This local topography is smoothed by the contouring program used. Fault scarps are also minimized. A virtual absence of published seismic reflection data limits direct mapping of basement faults across the basin floor. Notable exceptions are the delineations of the southern Alberta rift (Kanawasieh, 1968) and the Churchill-Superior Boundary zone (Hajnal and Fowler, 1982).

The western margin of the Shield adjacent to the WCSB is cut by a number of faults and shear zones of regional extent. At Great Slave Lake, the topographically distinct McDonald fault (MEE, Fig. 5.1) is one of a series of northeast-trending, brittle zone, late Hudsonian lineaments (Henderson et al., 1990). All of these run subparallel to the older Great Slave Lake shear zone (GSL-SZ). The dextral movement of the GSL-SZ is also characteristic of the Black Bay fault, the Virgin River shear zone and the Needle Falls shear zone (Fig. 5.1). This entire segment of the crust appears to have been subjected to a similar stress field at about 2000 Ma (Byers, 1962).

The Churchill-Superior boundary zone (CSBZ) is interpreted by Bleeker (1996) as a zone of collision with sinistral transcurrent movement. The north-trending Allan fault zone is early Hudsonian in age and has been subjected to recurrent movement after regional metamorphism. The Taberbrook fault defines the eastern boundary of the Archean Gneiss Lake domain, within the Trans-Pecos gneiss belt (Meyer, 1996).

The northeast-trending faults of the East Arm of Great Slave Lake continue in the subsurface as the Taltihna (TZT) and Hay River fault zones (HZT; Williams, Fig. 2, 1990). The GSL-SZ can be traced as far west as the eastern edge of the Cordillera by its aeromagnetic signature (Ross et al., this volume, Chapter 4). Conjugate northeast-northwest-trending faults control the basement topography and sedimentation patterns over the Peace River Arch (Cant, 1988). Vertical movements totalling several hundred metres along these faults in late Paleozoic time. In northwestern Alberta, a series of north-south lineaments, offset by later north-east-trending faults, were inferred by Garland and Brown (1959).

Offsets in linear gravity anomalies were used by Gent (1987) to define fault trends in the subsurface of Saskatchewan. These faults bear little obvious relation to those mapped on the exposed Shield. A set of conjugate north-northwest-trending faults, represented by Tanunda and Canol faults, represent the late, brittle stage of deformation of the THO. The position of the CSBZ in the subsurface is now defined (Weber, 1990). This boundary zone may have been active in Paleozoic time as indicated by the disturbance of Paleozoic strata.

The fundamental cause of the differential uplift of arches, especially the Peace River Arch, has been a subject of continued discussion. Burwash and Krupicka (1975) suggest isostatic control. Cant (1988) and Stephanoff and de Freitas (1989) favour crustal flexure related to the Cordilleran tectonics. Ross (1990) suggests that the Arch reflects a passive, flexural-isostatic feature rather than an area of thermal-ex- tensional tectonics.

Petrology

Data presented here are based primarily on Precambrian basement core samples accumulated at the University of Alberta over four decades. Burwash (1986) used cuttings to define the subsurface lithological belts of southwestern Manitoba, and Ross et al. (1989) separated zircons from cuttings from Alberta wells for U-Pb isotopic analyses.

Petrography

Basement lithology is mapped in Figure 5.2 and the legend for the figure is adopted from Burwash et al. (Fig. 3.10, in press). This manuscript also contains an extended discussion of the distribution and abundance of the data. The most abundant rock types are quartz-feldsparic greisens (36%), granitoids (16%), granulites (5%), metasedimentary rocks (5%), mylonites (5%) and amphibolites (3%). Recent U-Pb isotopic petrography by Burwash and Power (1991) suggests that the true abundance of granulites and retrogranulites may be closer to 10%.

Although the abundance of rock types varies spatially, defining boundaries between terranes on this basis is difficult. High grade metamorphic and/or deeply-seated igneous rocks are dominant in all areas. Classifications based purely on petrology are inadequate because many of the rocks show evidence of deformation subsequent to their original crystallization. The post-crystallization deformation is in turn accompanied or followed by recrystallization (Burwash and Krupicka, 1969; Burwash, 1978). The semigraphite display of deformation and recrystallization developed by Burwash and Krupicka (op. cit.) thus become critical factors in our petrographic classification. A comparison can be made between subsurface extensions of the THO and the northern Alberta belt, which includes the Peace River Arch (Athabasca Polytemporal, Trans-Pecos gneiss belt of Burwash et al., in press). In the buried THO, Precambrian supracrustal rocks (schist, banded iron formation, and metamorphics) form nearly 30% of the samples, compared to about 40 percent for gneisses and granitoids. In the APT, supra-crustal rocks form less than five percent and gneisses and granulites more than 80 percent. The APT has thus been eroded to a much deeper crustal level than the THO.

Geochemistry

For the purpose of multivariate analysis, data from analyses of whole-rock samples for selected minor and major elements were combined with petrographic data by Burwash and Culbert (1976). The two most useful methods proved to be R-mode and canonical analysis. Figure 5.3 shows the correlation of variables with the strongest R-mode factor, which is designated K-metal Tasmania. Figure 5.4 is a trend surface map generated for this factor (1A in Fig. 1; Burwash and Culbert, 1976).

Canonical trend analysis differs from R-mode analysis in its inclusion of X-T geographic coordinates as variables. By using this technique, canonical coefficients are determined (Fig. 5.5) and mapped as a trend surface (Fig. 5.6). The geological process identified is again K-metasomatism; the geographic area is a northeast-trending belt across northern Alberta. On both petrographic and geochemical grounds the Peace River Arch and its flanks are distinct from adjacent terranes.

Geochronology

The K-Ar, U-Pb, and Ar-Ar methods of isotopic age determination have been applied to regional studies of the WCSB (Figs. 5.7, 5.8, 5.9). Rb-Sr dating has been used at a few localities. Each method provides a valuable, but different, kind of information. K-Ar age determinations were used in the 1950s and 60s as a rapid reconnaissance tool to outline the main structural provinces of the buried and exposed Canadian Shield (Burwash et al., 1962; Stockwell, 1963; Wanless, 1979). For biotite, the most widely used mineral, the blocking temperature for escape of radiogenic argon is approximately 300°C. In regional studies, the dates obtained represent the time of uplift of that crustal segment above the 300°C isotherm. The K-Ar method, when applied to the WCSB, identified the extensional phases of the Taltihna (Triassic) and the Northwest Territories (Archean Superior Province) belts of southwestern Manitoba (Petersen, 1962). Three horblende separations from north-central Alberta have values of 2080 to 2200 Ma. These are assumed to be indicators of an older crustal element. The remainder of the floor of the basin cooled during the time interval from 1800 to 1750 Ma (Fig. 5.7).

U-Pb isotopic analysis of zircon provide a method of high resolution that can be applied to small volumes of rock, such as oil well drill cuttings (Figs. 5.8, 5.9). Ross et al. (1989) used data from cores and cuttings from Alberta wells and supplementary aeromagnetic data to define basement domains. The U-Pb dates are inferred to be the times of crystallization of the zircons from a magma, or the culmination of a metamorphic event. The histogram in Figure 5.10 adds Saskatchewan data from Collerson et al. (1988) to that of Ross et al. (1989).

The distribution of U-Pb zircon data shows two peaks between 2000 and 1750 Ma (Fig. 5.10). The early Hudsonian (2000-1900 Ma) samples are more numerous than the late Hudsonian (1860-1750 Ma). Kenoran events (2650-2550 Ma) are represented and are distinct from an earlier event characteristic of the northern extension of the THO. The map of U-Pb zircon ages for Alberta and Saskatchewan shows a broad zone of zircon ages from the 2500 to 2400 range that granitoids are well documented in northwestern Saskatchewan (Koster and Brandgaard, 1976). A more detailed map (Burwash et al., 1985) shows the adjacent Northwest Territories (Banks, 1980).
Figure 3.1 Precambrian basement structure, showing major observed faults on the exposed Shield and inferred faults in the buried Shield.
Figure 5.2 Lithology of Precambrian core samples from the Western Canada Sedimentary Basin.
Between 2350 and 2000 Ma the WCBS histrogram of U-Pb zircon age determinations shows a maximum at approximately 2200 Ma. Ross et al. (1980) interpreted this as the time of formation of the Buffalo Head Domain, a recently identified crystalline segment in northern Alberta. An alternative explanation is provided by Bos\-tock et al. (1991), working in the eastern foreland of the Talison magmatic arc of the Northwest Territories, and by Dickson et al. (1990), working in the Mudjatich belt of northwestern Saskatchewan. Both attribute a number of U-Pb ages, which fall in the 2400 to 2000 Ma range, to the inheritance of Archean lead in zircons recrystallized during the Hudsonian.

The Sm-Nd isotopic data shown on Figures 5.9 and 5.10 is the inferred time of separation of zylic crustal material from the mantle and is usually referred to as the time of crustal residence (t<sub>c</sub>). Early work by DeWolfe and Wasserburg (1970) used a mantle composition modelled on chondritic meteorites (CHUR). A depleted mantle model (Goldstein et al., 1984) is currently favoured and is used to determine all ages shown on the histogram in Figure 5.10 (Frost and Burwash, 1986; Collerson et al., 1988; Théberge and Ross, 1991). Depleted mantle model ages (t<sub>c</sub>) from the WCBS fall in the range 3400 to 2400 Ma, with a peak at about 2600 Ma, the time of the Kenoran Orogeny. The 2500 Ma event indicated by U-Pb data is also reflected in the Sm-Nd histogram. The values in excess of 3000 Ma may reflect the inheritance of Nd from Middle or Early Archean crust, as is the case in the northern Slave and western Superior provinces, or they may represent an inappropriate choice of mantle model.

Archean crust, or an Archean crustal component, occurs at all the dated localities plotted in Figure 5.9. Varying ratios of juvenile Proterozoic material have been added to the Hudsonian magmatic arcs (Collerson et al., 1988; Théberge and Ross, 1991). The Sm-Nd data thus support the concept of crustal recycling by deformation and metamorphism suggested by Burwash and Krupicka (1969, 1970).

### Meteorite Impact Zones

Several areas of marked local topographic relief on the Precambrian surface can be recognized in the WCBS. One of these, near Lake St. Martin, Manitoba (LSMS, Fig. 5.1), brings Precambrian basement to the surface in an arcuate pattern (Manitoba Mineral Resources Division, 1979). Shocked granite at this site, with a 2387 Ma K-Ar biotite age, is inferred to be part of a meteorite impact ring structure (McCabe and Bannatyne, 1977). Two Precambrian granulite inliers near High Rock Lake, south of Lake St. Martin, suggest a circular feature of very complex origin (McCabe, 1981, 1982).

An arcuate pattern is inferred for the Steen River Impact Structure (SRS, Fig. 5.11) located in northwestern Alberta. The SRS is a circular basement feature, 25 km in diameter. A central uplift raises fractured, partly melted basement 800 to 1000 m above the regional level. This is surrounded by a rim syncline, which locally downdrains the basement by more than 50 m. A raised rim forms a positive feature of a few tens of metres, and the whole is surrounded by an irregular disturbed zone extending up to 30 km from the centre. This disturbed zone may contain a second raised rim.

In addition to the basement, at least 1000 m of Devonian carbonates, evaporites and shales are tectonically disturbed by the structure. The SRS was only slightly modified by the pre-Cretaceous unconformity prior to the deposition of about 200 m of mid-Creta- ceous marine shale. Seismic sections across the structure show a pattern of small-scale normal faults forming horsts and grabens in the disturbed zone and cutting the raised rim. Within the rim syncline, the structure is extremely complex, with overthrusting disturbing and inverting the normal stratigraphic succession.

The SRS may have been modified by post-impact movement on the subsurface extension of the GSLZ and the faulted boundary between the Humber Terrane and the Great Bear Magnetic Arc. Motion on these features may have been triggered by the impact. Hydrocarbon-rich structural traps, both within the SRS and along the GSLZ, may be the result of this impact event.

Evidence for an extraterrestrial origin for the SRS is limited to the overall shape of the structure and study of the mineralogy and shock metamorphic textures within the central uplift (Carrigy, 1968; Winkler, 1972). K-Ar dating of partially melted basement indicates an age of 95±7 m.y. for the impact (Carrigy, 1968).

The SRS is intriguingly close in age to the similar Bofors structure in the Ukraine (1055 Ma), and may be evidence of a multiple impact event at that time. It also has apparent similarities to the larger Montague structure on the Scotian Shelf. This may be due to them both being the result of marine impacts. The presence of hydrocarbons within the SRS also invites comparison with well known hydrocarbon producers such as Red Wing Creek in South Dakota and Viewfield in Saskatchewan. The continued study of the SRS will shed light on the recognition and economic potential of buried basement features within the WCBS.
Discussion

Any preparation of a geological map of the subsurface Precambrian of the WCSB must be based on all available geological and geophysical data. In the absence of the constraints imposed by outcrop mapping, rational models are also essential. Our model is based on two salient hypotheses. The first suggests that most of the WCSB is floored by rocks that formed during either the Kenoran or Hudsonian orogenies (as defined by Strockwell, 1963), or that they are Archean or Lower Proterozoic rocks that have been exposed to Hudsonian metamorphic overprinting. The second hypothesis, supported by Sm-Nd isotopic data, indicates that almost all of the WCSB is underlain by sialic crust that was differentiated from the mantle during the Archean, with linear belts to which a significant juvenile Proterozoic component has been added.

The Kenoran rocks (2800 - 2400 Ma) include volcanic belts and their related hypabyssal intrusives, major batholithic complexes and, finally, the uplifted granulite blocks common in northern Saskatchewan and adjacent Alberta and the Northwest Territories. Early and Middle Archean rocks (2400 Ma) occur in the exposed parts of the Slave, Superior and Wyoming provinces. The northern extension of the Wyoming craton into southern Alberta is indicated by a U-Pb zircon age of 3278 ± 22/21 Ma from a basement core at 49°44'N, 111°26'W (Villeneuve et al., in press). The Slave and Superior provinces extend beneath the Phanerozoic cover of the southern District of Mackenzie and southwestern Manibouche (Fig. 5.12).

Three Hudsonian magmatic belts can be traced from the exposed Shield beneath the WCSB. To the west of the Slave Province, the Wipwapi Orogenic (WMO) extends beneath the cover rocks of the Northern Interior Plains and is truncated by the TEZ and HRZ, and by the GSLZ. The southern continuation of the WMO probably occurs near the Alberta-British Columbia boundary, west of the Archean core sample, along the GSLZ (Fig. 5.8). To the east of the Slave Province, the Thelon Tectonic Zone (TTZ) is offset along the Bathurst and McDonald fault systems. Its southern extension, the Talson Magnetic Zone (TMM) (Bostock et al., 1991) can be traced southward from the GSLZ to the Snowbird Tectonic Zone (STZ, Fig. 5.13).

The thermal axis of the TTHO in Saskatchewan and Manitoba is defined by the linear Wathaman batholiths (Staufier, 1984). The subsurface extension of the TTHO has been linked to the North American Central Plains conductive anomaly, but a causal relation between the two is difficult to establish (Burwash et al., in press). The Swift Current area of southwestern Saskatchewan has a number of Hudsonian epizonal plutons and volcanic centres younger than, but texturally aligned with, the Wathaman batholith. The tectonic significance of the Willington volcanic centre east of Edmonton (Burwash, 1955, 1957) remains obscure.

Acknowledgements

Many Canadian oil companies have provided basement core samples to the University of Alberta collection. The staffs of the ERCB Core Research Centre, Calgary, and the Subsurface Geological Laboratory, Regina, provided generous help to R.A. Burwash on his numerous collecting trips. Financial assistance has been provided by the National Science and Engineering Research Council, the Geological Survey of Canada and the University of Alberta Research Fund.

Numerous individuals who have assisted the basement studies are gratefully acknowledged. They include H. Baasgaard, Z.E. Peter- man, J. Kraupicka, R.R. Culbert, C.R. Steck, E.R. Kanasewic, A.G. Green, A.M. Jessop, G.M. Ross, C.D. Frost and P.A. Cavell. Special thanks go to Ruth W. Burwash, who assisted in sample preparation, and edited and transcribed the manuscript.
